ABSTRACT

We present a fully automatic computational vascular morphometry (CVM) approach for the clinical assessment of pulmonary vascular disease (PVD). The approach is based on the automatic extraction of the lung intraparenchymal vasculature using scale-space particles. Based on the detected features, we developed a set of image-based biomarkers for the assessment of the disease using the vessel radii estimation provided by the particle's scale. The biomarkers are based on the interrelation between vessel cross-section area and blood volume. We validate our vascular extraction method using simulated data with different complexity and we present results in 2,500 CT scans with different degrees of chronic obstructive pulmonary disease (COPD) severity. Results indicate that our CVM pipeline may track vascular remodeling present in COPD and it can be used in further clinical studies to assess the involvement of PVD in patient populations.

Index Terms— Scale-space, vessel segmentation, biomarkers, pulmonary vascular disease, COPD, CT

1. INTRODUCTION

It is estimated that 30 to 70% of subjects with advanced chronic obstructive pulmonary disease (COPD) have clinically significant pulmonary vascular disease (PVD). PVD is in part mediated by vascular remodeling including inflammation and endothelial dysfunction present even in smokers with normal lung function [1]. Although histopathology can be used to assess vascular remodeling in small sample sizes, volumetric computed tomography (CT) offers an unique opportunity to explore PVD based on vascular morphometry.

Under a computation vascular morphometry paradigm, the interplay between vessel cross-sectional area, blood volume and vessel lengthening are factors that can help to characterize PVD. Multiple approaches have been introduced for

the extraction of pulmonary vasculature based on either features from the Hessian [2, 3, 4] or waterfront propagation [5]. Although these techniques show acceptable performance they require additional steps for the quantification of vessel diameter. Additionally, accurate tree extraction for smaller vessels and robustness to noise remain as important issues. Moreover, the evaluation of vascular extraction algorithms remain a difficult challenge due to the complexity of the tree and the lack of labeled volumes.

In this paper, we present a technique for automatically extracting vessel location and caliber based on scale-space particles. Scale-space particles leverage the well-known theory of linear scale-space to localize features described by the Hessian. Unlike previous approaches, our technique has the unique ability to directly sample the vessel centerline and provide vessel size by exploiting the relationship between scale and physical radius. This is achieved in a computationally efficient framework inherent in the particle system. We exhaustively evaluate our algorithm's performance using simulated phantoms that exhibit complexity resembling real vasculature and thus demonstrate its effectiveness for CVM. Another major contribution of this work is also the introduction of a set of biomarkers for the assessment of PVD that are based only on information provided by scale-space particles.

2. METHODS

We start first by introducing the scale-space particle approach. We then derive the relationship between scale and vessel radii that can be used to obtain physical morphometric measures. Finally, we present the biomarkers that have been developed for the assessment of PVD.

2.1. Vessel detection by scale-space particles

Our vascular morphometry pipeline is based on scale-space particles [6]. Scale-space particles offer the possibility of efficiently exploring an image region for features, in our case vessels, that can be described by the Hessian. We detect ves-

This work has been supported by grants from the National Institutes of Health (K25 HL104085 to Dr. San José Estépar; K23 HL089353, to Dr. Washko; U01 HL089897 and U01 HL089856, to COPDGene). The authors would like to thank to all the COPDGene Investigators for their contributions and the data that was used in the paper.

sels as intensity ridge lines, using the ridge line definition as a point where the gradient is orthogonal to the two Hessian eigenvectors associated with the smallest (most negative) eigenvalues $\lambda_3 < \lambda_2$. Within the context of our particle system, points are moved onto ridge lines by repeated Newton optimization, which is completed at every energy-minimizing iteration of the particle system. To ensure that vessels of all radii are detected, we initialize the particle system with a uniform dense sampling of particles across the four-dimensional domain (three spatial axes and one scale axis).

The particle system solution is computed iteratively to minimize the system energy, which is a sum of inter-particle energy and energy associated with a particle's location within the image domain. The inter-particle energy is a quartic polynomial with a tunable potential well, chosen to quickly induce regular sampling. The potential well also serves the purpose of making particle population control (adding particles to fill gaps in the vessel sampling) part of the same over-all energy minimization that moves particles into a uniform sampling. Particles are removed when the strength of the ridge line feature (as quantified by the middle Hessian eigenvalue λ_2) falls below a pre-specified threshold that depends on image contrast. Following the general guidelines of [6], particle system computation proceeds in three steps: densely and uniformly sampling the two-dimensional manifold swept out in scale-space by the ridge lines, moving points to the scale of maximal feature strength, and then redistributing points to create a uniform vessel sampling.

2.2. Vessel sizing

Vessel radius can be analytically related to the scale by finding the value of σ that maximizes the multi-scale strength function, $R(\sigma) = \sigma^2 \lambda_2(\sigma)$, at the vessel center. Assuming that the vessel cross-section can be modeled as a disk with constant intensities inside and outside and that the CT point spread function behaves as a Gaussian of standard deviation σ_0 , the signal intensity is defined by the convolution integral as

$$f_\sigma(x, y) = \int_{-r}^r \int_{-\sqrt{r^2-v^2}}^{\sqrt{r^2-v^2}} G_\sigma(x+u)G_\sigma(y+v)dudv, \quad (1)$$

with $G_\sigma(x) = \frac{1}{\sqrt{2\pi}\sigma} e^{-\frac{x^2}{2\sigma^2}}$. Let us denote $F_\sigma(x) = \int_{-\infty}^x G_\sigma(t)dt$ for different scanner models (Fig. 1a). The scanner point spread function (PSF) was simulated by means of a convolution with a Gaussian function with standard deviation σ_b and noise was simulated as additive Gaussian noise with standard deviation σ_n . The background was set to -800 HU and the cone density to 100 HU to capture the nominal range of background/vasculature density in the lung. The cone was sampled in a high resolution grid and down-sampled with a windowed sinc resampling kernel into a 51x51x340 grid.

$$f_\sigma(x, y) = \int_{-r}^r G_\sigma(y+v)H_\sigma(x, v)dv \quad (2)$$

where $H_\sigma(x, v) = F_\sigma(x + \sqrt{r^2 - v^2}) - F_\sigma(x - \sqrt{r^2 - v^2})$. Since $\frac{\partial F_\sigma}{\partial x} = G_\sigma$,

$$\frac{\partial^2 f_\sigma}{\partial x^2}(x, y) = \int_{-r}^r G_\sigma(y+v)H_\sigma''(x, v)dv, \quad (3)$$

where $H_\sigma''(x, v) = G_\sigma'(x + \sqrt{r^2 - v^2}) - G_\sigma'(x - \sqrt{r^2 - v^2})$. At the center of the disk, the second order derivative in any

direction will also be equal to λ_2 , so

$$\lambda_2(\sigma)(0, 0) = \int_{-r}^r G_\sigma(v)2G_\sigma'(\sqrt{r^2 - v^2})dv, \quad (4)$$

since G_σ' is antisymmetric and $G_\sigma'(x) = \frac{-x}{\sigma^2}G_\sigma(x)$

$$R_\sigma(0, 0) = \frac{-1}{\pi\sigma^2}e^{-\frac{r^2}{2\sigma^2}} \int_{-r}^r \sqrt{r^2 - v^2}dv. \quad (5)$$

The term $\int_{-r}^r \sqrt{r^2 - v^2}dv$ can be easily computed with a change of variable and is equal to $\frac{\pi r^2}{2}$, so $R_\sigma(0, 0) = \frac{-r^2}{2\sigma^2}e^{-\frac{r^2}{2\sigma^2}}$ which has a maximum at $r = \sqrt{2}\sigma$. Since our model integrates an initial Gaussian convolution of σ_0 , we finally have the following relationship between the detected scale, σ , and the radius of the structure at the center of the cross-section given by

$$r = \sqrt{2}\sqrt{\sigma_0^2 + \sigma^2}. \quad (6)$$

2.3. Biomarkers Computation

Each particle has a given cylindrical volume corresponding to the cross sectional area defined by its scale and the length of the sampling given by the location of the potential well. From this, the distribution profile of blood volume as a function of the vessel cross sectional area can be computed and the blood volume for vessels less than 5 mm^2 (BV5) and larger than 10 mm^2 (BV10) can be calculated by integration of the distribution profile. The limits 5 mm^2 and 10 mm^2 define the transition between distal and proximal vasculature as previously defined in the literature [7]. Those quantities normalized by the total intraparenchymal blood volume can serve as CT-based biomarkers of vascular remodeling.

3. RESULTS

Evaluation framework. We designed two experiments to assess how accurate we can capture and quantify the vascular tree morphometry. The first experiment aimed at testing the validity of eq. (6) using a circular cone phantom with a linear radius ramp from 0 pixels to 8 pixel units simulated for different scanner models (Fig. 1a). The scanner point spread function (PSF) was simulated by means of a convolution with a Gaussian function with standard deviation σ_b and noise was simulated as additive Gaussian noise with standard deviation σ_n . The background was set to -800 HU and the cone density to 100 HU to capture the nominal range of background/vasculature density in the lung. The cone was sampled in a high resolution grid and down-sampled with a windowed sinc resampling kernel into a 51x51x340 grid.

The second experiment was based on the Vascusynth simulator [8]. Vascusynth was used to generate trees of multiple complexities by changing the number of terminal nodes

from 5 to 1000 within a volume of $100 \times 100 \times 100$ voxels of 0.6 mm. Lung parenchyma was simulated by means of a Gaussian process with mean -800 HU and standard deviation of 150HU spatially correlated with a Gaussian kernel with std 1.5 pixel. The vessel maximum density was set to 100 HU. Gaussian noise of $\text{std}=20\text{HU}$ was added to the final image to account for the noise levels typically encountered in high-dose CT scans. The segmentation quality was assessed by comparing the results with the graph tree produced by Vasusynth. Particle points that were less than 0.6 mm to the closest ground truth point were true positive results, otherwise the points were marked as false positives. False negative points were computed by finding the ground truth points that did not have a particle point at a distance less than 0.6 mm.

For all the experiments, scale-space particles were run with the same experimentally selected parameters. The threshold on λ_2 was -20, the number of iterations for each step were 80, 20 and 60 respectively. The energy blending parameters as defined in [6] were $\alpha = 1, \beta = 0.7$ for step 1, $\alpha = 0, \beta = 0.5$ for step 2 and $\alpha = 0.25$ and $\beta = 0.25$ for step 3. These values achieved the desired repulsion/attraction behavior for each step. For all cases, the scale-space particles were initialized by seeding on a initial mask obtained by an upper threshold of the original image with value -500HU.

Radius estimation validation. Scale-space particles were run in the simulated cone volumes and the relative estimation error between the real radius at the location of the particle (given by its z-coordinate) and the estimated radius based on eq. (6) was computed for different scanning scenarios (Fig. 1). Fig. 1b shows that the error has two linear sections with a breaking point corresponding to the resolution of the CT scanner given by the width of the PSF. Even for the ideal imaging system, $\sigma_b = 0$, there is an inflection point at 1 pixel radius reflecting the Nyquist limit. Note that particles were not placed at cone sections with low radius as σ_b increases suggesting the limited capturing range as the PSF is smoother and smoother. Fig. 1c shows the error for different noise levels. It is interesting to note the robustness of scale-particles to Gaussian noise both in radius estimation and capturing range.

Geometry extraction validation. Table 1 shows the accuracy, precision, sensitivity and specificity of scale-space particles for vascular tree segmentation as the geometry of the tree increases in complexity as depicted in Fig. 2. The results show that our method consistently has a specificity and precision higher than 95% for all complexity levels. Accuracy and sensitivity decreases as the number of terminal nodes is greater than 300 in part due to the increment of smaller vessels that are harder to extract (the mean tree radius decrease from 2.41mm for 5 terminal nodes to 0.6 mm for 1000 terminal nodes). Even though, for a highly complex tree with 1000 terminal nodes, our method's accuracy still remains at 77%. It also worth noting that the computational cost of our method is in the order of minutes for a volume of $100 \times 100 \times 100$ and the

execution time has a logarithm relation with tree complexity.

Real cases. The proposed method has been used to extract the vasculature of 2,500 CT scans from the COPDGene cohort. The CT scans were acquired at inspiration with a dose level of 200 mAs and a smooth reconstruction kernel (B31f and Bone for Siemens and GE scans respectively). For each case, the distribution of blood volume with respect to the vessel cross sectional areas was computed using the estimated radius. Fig. 3 shows the result for two extreme cases corresponding to smokers with different emphysema severity. Fig. 4a-b shows the intraparenchymal blood volume distribution for those same cases. It is worth noting the shift in the blood volume profile for the selected cases suggesting that proximal vasculature dilates to compensate for the increase in resistance. This can be corroborated in Fig. 4c that shows the relation between $\text{BV}_{10}/\text{TBV}$ and BV_5/TBV across the 2,500 cases analyzed.

4. DISCUSSION AND CONCLUSIONS

We have presented an algorithm for the extraction and quantification of the pulmonary vasculature that can be used within a computational vascular morphometry framework for the study of pulmonary vascular disease. Scale-space particles appear to be a suitable strategy for this task as supported by our results. The radius estimation provided by the scale esti-

mation holds for vessel sizes that are larger than the width of the PSF under Gaussian assumptions. The proposed method is also robust against Gaussian noise for the SNR range that can be typically found in clinical CT. The accuracy and precision of our method depend on the tree complexity and are bounded by the CT resolution. Further analysis includes the validation of this technique with real data and the relation of the proposed biomarkers with physiological markers of PVD and clinical outcomes.
